## Online Technical Appendix A <br> Performance of the Weighted Exogenous Sampling with Bayesian Inference (WESBI) Method

In this technical appendix, we examine the efficacy of the Weighted Exogenous Sampling with Bayesian Inference (WESBI) method for estimating a proportional hazard network growth model. We conduct a comprehensive simulation study covering a large variety of possible network structures characterized by different parameter values. For each network structure, we show that by sampling a small proportion of the total observations, we can recover the true network generating parameters with very high accuracy.

The basic simulation process for each of the sets of parameter values we use is the following: First, we simulate a network according to the parameter values in the set. Second, we consider different sampling proportions of this simulated network; for each sampling proportion, we sample the simulated network 25 times and estimate the model using the WESBI method. For each of the different sampling proportions, we report the average posterior means and average posterior standard deviations of the parameter estimates across the 25 estimations.

We consider a total of 56 different sets of parameter values. To investigate the performance of the WESBI method on different network structures, we conduct experiments in two distinct categories of networks: networks with long tails and networks without long tails, as determined by the in-degree distribution. Because the long tail is a characteristic found in most online social networks, we use the first 32 experiments to show the performance of the WESBI method under various parameter combinations that lead to networks with long tails. For the following 24 experiments, we focus on the performance of the WESBI method for networks without long tails. The skewness of the in-degree distribution in our Epinions.com dataset lies within the range of skewness levels of the simulated networks we consider. This suggests that the WESBI method is appropriate to use for our research context.

## Network Generation Process

We simulate networks by using a variation of the classic Barabasi and Albert (1999) model. There are initially $m_{0}$ isolated nodes in the network at time $t=0$, and $m$ nodes are added into the network in each time period for $T$ time periods. Subsequently, we allow the network to evolve further by allowing the tie-formation process to continue for $K$ additional time periods.

The expressions below specify the proportional hazard process governing the formation of a directed link from node $i$ to node $j$ :

$$
\begin{align*}
\lambda_{i j} & =\lambda_{0} \exp \left(\beta_{1, i} z_{1, j}+\beta_{2, i} z_{2, j}\right), \quad \lambda_{0}>0,  \tag{1}\\
\boldsymbol{\beta}_{i} & =\left[\begin{array}{l}
\beta_{1, i} \\
\beta_{2, i}
\end{array}\right]=\boldsymbol{\delta}+\boldsymbol{\varepsilon}_{\boldsymbol{i}}=\left[\begin{array}{l}
\delta_{1} \\
\delta_{2}
\end{array}\right]+\boldsymbol{\varepsilon}_{\boldsymbol{i}}, \quad \boldsymbol{\varepsilon}_{\boldsymbol{i}} \sim \operatorname{MVN}\left(0, \boldsymbol{\Sigma}_{\beta}\right) .
\end{align*}
$$

In the above, $\lambda_{0}$ is the baseline hazard rate which describes the inherent propensity of individual $i$ forming a link with $j$ without considering other factors and is independent of time. $z_{1, j}$ and $z_{2, j}$ are two different timeconstant characteristics for individual $j$. Individual specific coefficients $\boldsymbol{\beta}_{i}$ capture how covariates have different impacts on individual tie-formation decisions across people. The quantity $\exp \left(\beta_{1, i} z_{1, j}+\beta_{2, i} z_{2, j}\right)$ increases or decreases the baseline hazard rate of tie formation between $i$ and $j$.

## Simulation Design for Long-Tailed Networks

It has been observed that many complex networks, especially online social networks, have long-tailed degree distributions (Barabasi and Albert 1999; Mislove et al. 2007). As a result, it is especially important to study the performance of the WESBI model for networks with long tails.

To generate the networks, we set $m_{0}=1, m=1$. To compare how our model adapts to networks of different sizes, we set $T \in\{2000,5000\}$, resulting in networks of size 2001 or 5001 , and set $K=200$. We set $\lambda_{0}$ to be a very small number so that the rate at which ties are formed is slow and the simulated network
are relatively sparse. Specifically, we set $\lambda_{0} \in\left\{e^{-50}, e^{-55}\right\}$ (i.e., $\log \lambda_{0} \in\{-50,-55\}$ ). For the parameters, $\beta_{1, i}$ and $\beta_{2, i}$, we set $\delta_{1} \in\{-2,-3\}, \delta_{2} \in\{2,3\}$. The variance-covariance matrix of the coefficients are set to be the same across all simulated networks: $\boldsymbol{\Sigma}_{\boldsymbol{\beta}}=\left(\begin{array}{cc}1 & 0.5 \\ 0.5 & 1\end{array}\right) \times 0.5$.

We employ two scenarios for the distributions of individual characteristics. In the first scenario, individual characteristics, $z_{1, j}$ and $z_{2, j}$ are drawn from two independent distributions: $z_{1, j} \sim \operatorname{Exponential}(1) * \sigma_{z}, z_{2, j} \sim N\left(0, \sigma_{z}^{2}\right)$. In the second scenario, they are drawn from two independent distributions: $z_{1, j} \sim \mathrm{~N}\left(0, \sigma_{Z}^{2}\right), z_{2, j} \sim \mathrm{~N}\left(0, \sigma_{Z}^{2}\right)$. Note that, in the first scenario the distribution for one covariate is skewed and the distribution for the other is symmetric, while in the second scenario both distributions are symmetric. While the exponential and the normal distributions themselves are not long-tail distributions, the hazard model we employ here allows us to construct networks in which the distributions of node degree are long-tailed. Intuitively, this is because the hazard rate of extending links is proportional to the exponent of the covariate values. Thus, the impact on tie formation of covariates with large values will be greatly magnified, implying that there will be individuals who have a large number of incoming links and will therefore contribute to a long tail. To support this argument, in the following sections, we report the mean and the max of the degrees of the various networks we generate, and compare these statistics across networks with and without long-tailed distributions. The parameter $\sigma_{z}$ governs the variance of each distribution, and its value is set so that the generated networks are sparse.

We can vary the values of $T, \lambda_{0}, \delta_{1}, \delta_{2}$, and the distributions of the two covariates to generate networks with different characteristics. In this first simulation, we have $2^{5}=32$ different parameter combinations, i.e., we generate 32 different types of networks. As we can see from Table A2, the simulated networks cover a large variety of network structures. The size of the network is either 2001 or 5001, the maximum in-degree ranges from 441 to 1296 , and the network density ranges from $0.007 \%$ to $0.078 \%$. The low densities are representative of common online social networks such as the ones in our Epinions study. By setting the two factors $\delta_{1}$ and $\delta_{2}$ to have opposite mean impact ( $\delta_{1} \delta_{2}<0$ ), we can test the robustness of

WESBI on estimating parameters with different signs. Furthermore, we assume that different factors can have different average impact on the formation of ties $\left(\left|\delta_{1}\right| \neq\left|\delta_{2}\right|\right)$. Thus we can also investigate how well WESBI estimates model parameters when one factor dominates the other by varying the values of $\delta_{1}$ and $\delta_{2}$. While we fix the variance-covariance matrix of individual heterogeneous parameters, by changing the values of $\delta_{1}$ and $\delta_{2}$, we can also illustrate how the relative values in the variance-covariance matrix, compared with the mean values of the parameters, will influence the estimation results.

The conditional-log-likelihood function for the data in our simulations simplifies to the following (the notation is described in the paper):

$$
\begin{gathered}
\log L=w_{1}\left(\sum_{\left(\mathbb{I}_{i j}=1\right)}\left\{\log \left[1-\exp \left\{-\lambda_{0} \exp \left(\beta_{1, i} z_{1, j}+\beta_{2, i} z_{2, j}\right)\right\}\right]-\lambda_{0}\left(k_{i j}-1\right) \cdot \exp \left(\beta_{1, i} z_{1, j}+\beta_{2, i} z_{2, j}\right)\right\}\right) \\
+w_{0}\left(\sum_{\left(\mathbb{I}_{i j}=0\right)}\left\{-\lambda_{0}\left(k_{i j}-1\right) \cdot \exp \left(\beta_{1, i} z_{1, j}+\beta_{2, i} z_{2, j}\right)\right\}\right)
\end{gathered}
$$

Here, $w_{0}=\frac{1-Q_{1}}{1-H_{1}}$ and $w_{1}=\frac{Q_{1}}{H_{1}}$, where $Q_{1}$ is the fraction of the ties formed in the whole population, and $H_{1}$ is the fraction of the ties formed in the sampled dataset. For example, in a directed network with 2000 individuals, there are in total $3,998,000$ possible pairs that can form a tie. If 2,000 ties are formed, $Q_{1}=$ $\frac{2000}{3998000}=0.0005$. All observations where ties are formed are included in the sampled dataset, thus if we sample 100,000 pairs out of the $3,998,000$ possible pairs, $H_{1}=\frac{2000}{100,000}=0.02$. This gives $w_{0}=1.0199$, and $w_{1}=0.025$. By varying the fraction of dyads with ties formed in the sampled dataset we can explore how the effectiveness of the WESBI method depends on the number of sampled observations. We pick three possible values of the sampling proportion: $5 \%, 10 \%, 15 \%$, which means that we sample, respectively, $5 \%$, $10 \%$ and $15 \%$ of the total number of dyad pairs that do not form ties. Note that we always sample all the ties that are formed. For each sampling proportion of each network, we repeatedly sample the network 25 times, each time to obtain the target sampling proportion. We then estimate the model 25 times on the 25 samples
using the WESBI method. We report the average posterior means and the average posterior standard deviations of the parameter value estimates recovered from the 25 runs, and compare these results with the true parameter values that we used to generate the networks.

In summary, we are estimating the model on $32 \times 3=96$ different datasets, each 25 times. These 96 datasets show that the WESBI method recovers parameter values accurately and, therefore, works very well in a wide range of conditions.

| Network 32 | 3887 | 0.777 | 1118 | 1438.127 | $0.016 \%$ |

As we see from Table A2 above, while the mean in-degree for each of the 32 networks is less than two, the maximum in-degree for each network is two or three orders of magnitude larger. This is evident from the ratio between the max and the mean in-degree. For comparison, we simulate 500 scale-free networks with long-tailed in-degree distributions following the procedure in Barabasi and Albert (1999). ${ }^{1}$ The mean of in-degrees across the 500 networks is 1.00 , and the node with maximum in-degree across the 500 networks has an in-degree of 325 . By comparing statistics of the scale-free networks with those of our 32 simulated networks, it is clear that the long tail property is more salient in the 32 networks we simulated.

The 32 tables that follow show the estimation results from our simulation study. Each table reports parameter estimates for one set of parameter values. In each table, the first column reports the true parameter values used to generate the 25 sample networks. The second column reports the parameter estimates when $5 \%$ of the dyads that did not form a tie were sampled and used for parameter estimation; for each parameter, we report the average posterior mean and, in parentheses, the average standard deviation across the 25 instances. We put a check mark adjacent to these numbers if the true value of the parameter falls within the $95 \%$ credible interval that is constructed by using the average posterior mean and the average posterior standard deviation. Similarly, we report the parameter estimates when $10 \%$ and $15 \%$ of the dyads that did not form a tie were sampled for parameter estimation in the fourth and sixth columns, respectively.

The results show that sampling $10 \%$ or $15 \%$ of the dyads that do not form a tie gives very accurate estimation results with the true parameter value always falling in the credible interval. Even when we sample only $5 \%$ of the total dyads that do not form a tie, the true network parameter value falls in the corresponding

[^0]$95 \%$ credible interval approximately $75 \%$ of the time. These results show that we can estimate the parameters with high accuracy by sampling a relatively small fraction of the total network and using the WESBI method for estimation.

Network 1:

## Simulation Design for Non-Long-Tailed Networks

All generated networks in the preceding simulation exercise have a long-tailed degree distribution. While this characteristic is present in most online social networks, it is nonetheless important to demonstrate the performance of WESBI on networks that are of "short" tail. We conduct this exercise now. Following the same simulation scheme described above for networks with long tails, we vary the values of $T, \delta_{1}, \delta_{2}$, and the distributions of the two covariates to generate networks with different characteristics. Notably, we choose distributions for the individual characteristics, $z_{1, j}$ and $z_{2, j}$, such that the generated networks do not have long-tailed degree distributions.

Specifically, we consider three scenarios. In the first scenario, $z_{1, j}$ and $z_{2, j}$ are drawn from the following independent distributions: $z_{1, j} \sim \operatorname{Uniform}(-1,1) * \sigma_{z}, z_{2, j} \sim \operatorname{Uniform}(-1,1) * \sigma_{z}$. In the second scenario, $z_{1, j}$ and $z_{2, j}$ are drawn from the following independent distributions: $z_{1, j} \sim \operatorname{Uniform}(-1,1) *$ $\sigma_{z}+\mu_{z 1}, z_{2, j} \sim \operatorname{Uniform}(-1,1) * \sigma_{z}+\mu_{z 2}$, where $\mu_{z 1}<0$ and $\mu_{z 2}>0$. In the third scenario, $z_{1, j}$ and $z_{2, j}$ are drawn from the following independent distributions: $z_{1, j} \sim \operatorname{Uniform}(-1,1) * \sigma_{Z_{1}} \quad$, $z_{2, j} \sim \log$-normal $(0,1) * \sigma_{z_{2}}$. Note that in the first scenario the value of individual characteristics are bounded from above and the distribution is uniform, and thus we will not observe individuals with an exceptionally large number of incoming links. Correspondingly, networks generated according to the first scenario will not be long-tailed. In the second scenario, we assign a small value to $\sigma_{z}$ and set $\mu_{z 1}<0$ and $\mu_{z 2}>0$, which simulates networks which are significantly less heterogeneous and less skewed, i.e., with shorter tails, compared with those in the first scenario. In the third scenario, we consider "hybrid" cases in which the distribution of one individual characteristic is uniform and bounded from above, while the distribution of the other individual characteristic is skewed and not bounded from above (by virtue of being log-normally distributed). In a later part of this section, we use some statistics to show this "short tail" property in networks generated in these three scenarios.

In the simulation in this section, we have $2^{3} \times 3=24$ different parameter combinations, thus we generate 24 different types of networks. As we can see from Table A4, the simulated networks cover a large variety of network structures. The size of the network can be either 2001 or 5001, the maximum in-degree ranges from 9 to 347 , and the network density ranges from $0.007 \%$ to $0.090 \%$. Table A4 shows some statistics of the networks that are generated in these scenarios. As we can see, the maximum in-degrees of the 24 networks generated in these scenarios are significantly smaller than the maximum in-degrees of the 32 long-tail networks in Table A2. This suggests that the networks studied in this section have relatively "short" tails.

For further comparison, we plot the in-degree distributions of representative short- and long-tailed networks in Figure A1. We use data from Network 45 as an example of a short-tail network, and Network 25 as an example of a long-tail network. The $x$-axis shows the in-degree (exact in-degree when this value is $\leq 3$, and a range for larger in-degree, with the range progressively increasing), and the $y$-axis shows the frequency on a $\log$ scale. As we can see from Figure A1, the tail of the in-degree distribution for the short-tail network disappears even for small in-degree (the maximum in-degree is 9 in this case), while the tail of the in-degree distribution for the long-tail network extends to much larger numbers (the maximum in-degree is 836 in this case). By combining generated networks from all scenarios with both long tail and short tail, our simulation study covers a wide range of network structures in terms of their thickness of the tails of the in-degree distributions.

Table A3: Parameter Values Used to Simulate Non-Long-Tailed Networks

|  | $T$ | $\log \left(\lambda_{0}\right)$ | $\delta_{1}$ | $\delta_{2}$ | Distribution of Characteristics |

Figure A1: In-Degree Distributions for Representative Short- and Long-Tail Networks

For each target value of the sampling proportion ( $5 \%, 10 \%, 15 \%$ of the total dyads that do not form a tie) of the 24 networks, we repeatedly sample the network 25 times, and estimate the model on the 25 samples using the WESBI method. We report the average posterior means and the average posterior standard deviations of the parameter values recovered from the 25 runs, and check whether the true network generating parameters fall within the $95 \%$ credible intervals that are constructed using these values.

The 24 tables that follow show the estimation results, presented as before, from our simulation study. A check mark indicates that the true value of the parameter falls within the $95 \%$ credible interval that is constructed by using the average posterior mean and the average posterior standard deviation using estimates from the 25 runs. As before, the results show that sampling $10 \%$ or $15 \%$ of the dyads that do not form a tie gives very accurate estimation results with the true parameter value always falling in the credible interval. This shows that we can estimate the parameters with high accuracy by sampling a relatively small fraction of the total network and using the WESBI method for estimation.

## Overall Conclusions

We can make the following conclusions from the simulations:

- By sampling all the dyads that form ties and $10 \%$ (or $15 \%$ ) of the dyads that do not form ties, we can accurately estimate parameter values using the WESBI method.
- The average posterior standard deviation in parameter estimates grows smaller as we sample more data.
- For both long- and short-tailed networks, parameter estimation using the WESBI method is equally good, and we observe the same patterns as we sample more data.

## Estimation Time Advantage of the WESBI method

To assess the estimation time advantage of the WESBI method, we compare the average time taken by one iteration of the Bayesian inference procedure when the full dataset is used and when smaller sampled datasets are used. In the algorithm, the difference between the time taken by one iteration of the Bayesian inference procedure is very small regardless of whether the iteration belongs to burn-in phase or after the chains have converged. (The time taken is always within $\pm 9.3 \%$ of the average time taken by one iteration.) Thus we take the average across the first 1,000 iterations in the estimation procedure. In Table A5, we report the average time taken in seconds for completing the calculations of one iteration in the MCMC procedure of estimation from the full dataset and three different sampled datasets (sampling proportions are $5 \%, 10 \%, 15 \%$, respectively) for each of the 56 networks we generated above. As we stated, the variance in time taken across iterations is small within each sampled dataset, so the reported numbers are suitable for comparison. The numbers in parentheses in the last three columns denote the percentage time taken as compared to using the full dataset.

Table A5: Iteration Times for WESBI for Different Sampling Proportions

|  | Time per iteration with full dataset | Time per iteration when $5 \%$ of nontie dyads are sampled | Time per iteration when $10 \%$ of non-tie dyads are sampled | Time per iteration when $15 \%$ of nontie dyads are sampled |

## Online Technical Appendix B

## Random Coefficients Model

## Model Estimation

We extend our basic model to include individual-level heterogeneity. First, to capture unobserved heterogeneity in the baseline hazard rates across reviewers, we allow the parameter $\alpha_{1}$ of the baseline hazard function to vary across senders using a log-normal distribution in the following way: $\lambda_{0, i}(t)=\alpha_{0} \alpha_{1 i} t^{\alpha_{1 i}-1}$ and $\log \left(\alpha_{1, i}\right) \sim \mathrm{N}\left(\overline{\alpha_{1}}, \sigma_{\alpha}^{2}\right)$, where $i$ is the index over senders. (Note that the heterogeneity in $\alpha_{0}$ is absorbed by $a_{i}$, the sender-specific random effect.) Second, heterogeneity may exist because the same covariates may have different impacts on different reviewers' propensities to form trust relationships. To control for this, we allow for heterogeneity in the coefficients as follows: $\left[\begin{array}{c}\boldsymbol{\beta}_{i}^{i} \\ \boldsymbol{\beta}_{i}^{j} \\ \boldsymbol{\beta}_{i}^{i j}\end{array}\right]=\boldsymbol{\beta}_{i}=\boldsymbol{\delta}+\boldsymbol{\varepsilon}_{\boldsymbol{i}}, \boldsymbol{\varepsilon}_{\boldsymbol{i}} \sim M V N\left(0, \boldsymbol{\Sigma}_{\beta}\right)$. The notation used here is similar to that used in the homogenous model in Section 3 of the paper. Let $\mathrm{C}_{\mathrm{ij}}$ be the number of time periods for which dyad ij has been observed, and $\mathrm{T}_{\mathrm{ij}}$ be the length of time from the starting point to the time period when $i$ extends a tie to $j$. We define $\mathbb{I}_{i j}=1$ if $T_{i j} \leq C_{i j}$ (i.e., if a tie formed within the observation time) and 0 otherwise, and $\mathrm{k}_{\mathrm{ij}}=$ floor $\left(\min \left\{\mathrm{T}_{\mathrm{ij}}, \mathrm{C}_{\mathrm{ij}}\right\}\right)$. The log-conditional-likelihood function for this formulation is given by:

$$
\begin{aligned}
& \log L= \sum_{i=1}^{N} \\
& \sum_{j=1, j \neq i}^{N}\left\{\mathbb{I}_{i j} \log \left[1-\exp \left\{-\exp \left[\alpha_{i}\left(k_{i j}\right)+\boldsymbol{z}_{i j, k_{i j}} \boldsymbol{\beta}_{\boldsymbol{i}}+\boldsymbol{a}_{\boldsymbol{i}}+\boldsymbol{b}_{\boldsymbol{j}}+\boldsymbol{d}_{\boldsymbol{i} j}\right]\right\}\right]\right. \\
&\left.\quad-\sum_{t=0}^{k_{i j}-1} \exp \left[\alpha_{i}(t)+\boldsymbol{z}_{i j} \boldsymbol{\beta}_{\boldsymbol{i}}+a_{i}+b_{j}+d_{i j}\right]\right\}
\end{aligned}
$$

where $\alpha_{i}(t)=\ln \left(\int_{t}^{t+1} \lambda_{0, i}(u) d u\right)$. The results for the model with heterogeneity are provided in the table below. We find that the impact of preferential attachment and recency are qualitatively the same as in the model with homogenous individuals.

## Estimation Procedure

For the procedure described below, letters with superscript $u$ represent the values of the corresponding updated parameters.

Step 1: $\boldsymbol{\beta}_{i}^{u} \mid \boldsymbol{\delta}, \Sigma_{\boldsymbol{\beta}}, a_{i}, b_{i}, \alpha_{0}, \alpha_{1, i}, d_{i j}$, data

$$
\begin{aligned}
& f\left(\boldsymbol{\beta}_{i}^{u} \mid \boldsymbol{\delta}, \Sigma_{\boldsymbol{\beta}}, a_{i}, b_{i}, \alpha_{0}, \alpha_{1, i}, d_{i j}, \text { data }\right) \\
& \quad \propto \mathrm{N}\left(\left(\boldsymbol{\beta}_{i}^{u} \mid \boldsymbol{\delta}, a_{i}, b_{i}, \alpha_{0}, \alpha_{1, i}, d_{i j}\right), \Sigma_{\boldsymbol{\beta}}\right) L(\boldsymbol{Y}) \\
& \quad \propto\left|\Sigma_{\boldsymbol{\beta}}\right|^{-\frac{1}{2}} \exp \left[-\frac{1}{2}\left(\boldsymbol{\beta}_{i}^{u}-\boldsymbol{\delta}\right)^{\prime} \Sigma_{\boldsymbol{\beta}}^{-1}\left(\boldsymbol{\beta}_{i}^{u}-\boldsymbol{\delta}\right)\right] L(\boldsymbol{Y})
\end{aligned}
$$

where $L(\boldsymbol{Y})$ is the likelihood function. Since this distribution does not have a closed form, we use the Metropolis-Hastings algorithm to draw from the conditional distribution of $\boldsymbol{\beta}_{\boldsymbol{i}} \cdot \boldsymbol{\beta}_{\boldsymbol{i}}$ is the draw of coefficients from the previous iteration, and we draw $\boldsymbol{\beta}_{i}^{u}$ by $\boldsymbol{\beta}_{i}^{u}=\boldsymbol{\beta}_{\boldsymbol{i}}+\Delta \boldsymbol{\beta}$, where $\Delta \boldsymbol{\beta}$ is a draw from $\mathrm{N}\left(0, \Delta^{2} \Lambda\right)$, and $\Delta$ and $\Lambda$ are chosen adaptively to reduce the autocorrelation among the MCMC draws following Atchade (2006). The probability of accepting this $\boldsymbol{\beta}_{i}^{u}$, the updated value for $\boldsymbol{\beta}_{\boldsymbol{i}}$ is:

$$
\operatorname{Pr}(\text { acceptance })=\min \left\{\frac{\left[\exp \left(-\frac{1}{2}\left(\left(\boldsymbol{\beta}_{i}^{u}-\boldsymbol{\delta}\right) \Sigma_{\boldsymbol{\beta}}^{-1}\left(\boldsymbol{\beta}_{i}^{u}-\boldsymbol{\delta}\right)\right)\right] L\left(\boldsymbol{Y} \mid \boldsymbol{\beta}_{i}^{u}\right)\right.}{\left[\exp \left(-\frac{1}{2}\left(\left(\boldsymbol{\beta}_{i}-\boldsymbol{\delta}\right) \Sigma_{\boldsymbol{\beta}}^{-1}\left(\boldsymbol{\beta}_{i}-\boldsymbol{\delta}\right)\right)\right] L\left(\boldsymbol{Y} \mid \boldsymbol{\beta}_{i}\right)\right.}, 1\right\}
$$

Step 2: $\boldsymbol{\delta}^{u} \mid \Sigma_{\boldsymbol{\beta}}, \boldsymbol{\beta}_{i}^{u}$
$\boldsymbol{\delta}^{u}$ is generated from the distribution $\operatorname{MVN}\left(\boldsymbol{\mu}_{\boldsymbol{\delta}}, \boldsymbol{V}_{\boldsymbol{\delta}}\right)$, where $\boldsymbol{\mu}_{\boldsymbol{\delta}}=\boldsymbol{V}_{\boldsymbol{\delta}}\left[\boldsymbol{\Sigma}_{\boldsymbol{\beta}}^{-1} \sum_{i=1}^{N} \boldsymbol{\beta}_{i}^{u}+V_{0}^{-1} U_{0}\right], \boldsymbol{V}_{\boldsymbol{\delta}}=$ $\left(\boldsymbol{N} \boldsymbol{\Sigma}_{\beta}^{-1}+V_{0}^{-1}\right)^{\mathbf{- 1}}$. We define diffuse priors by setting $V_{0}=100 I$ and $U_{0}=0$.

Step 3: $\Sigma_{\boldsymbol{\beta}}^{u} \mid \boldsymbol{\beta}_{i}^{u}, \boldsymbol{\delta}^{u}$

$$
\left(\Sigma_{\boldsymbol{\beta}}^{u} \mid \boldsymbol{\beta}_{i}^{u}, \boldsymbol{\delta}^{u}\right) \sim \mathrm{IW}_{n(\boldsymbol{\beta})}\left(f_{0}+N, \boldsymbol{G}_{0}^{-1}+\sum_{i=1}^{N}\left(\boldsymbol{\beta}_{i}^{u}-\boldsymbol{\delta}^{u}\right)\left(\boldsymbol{\beta}_{i}^{u}-\boldsymbol{\delta}^{u}\right)\right)
$$

where we set $f_{0}=n(\beta)+5$ and $\boldsymbol{G}_{\mathbf{0}}=I_{n(\beta)}$ to be diffuse hyperpriors. $f_{0}$ is the degrees of freedom, $\boldsymbol{G}_{\mathbf{0}}$ is the scale matrix of the inverse-Wishart distribution, and $n(\beta)$ is the number of $\delta$ parameters, the ones before observed covariates that we are interested in.

Step 4: $\alpha_{1, i}^{u} \mid \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{0}, \overline{\alpha_{1}}, \sigma_{\alpha}^{2}, d_{i j}$, data

We can define the distribution of $\alpha_{1, i}^{u}$ as:

$$
\begin{aligned}
& f\left(\alpha_{1, i}^{u} \mid \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{0}, \overline{\alpha_{1}}, \sigma_{\alpha}^{2}, d_{i j}, \text { data }\right) \\
& \quad \propto \mathrm{N}\left(\left(\alpha_{1, i}^{u} \mid \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{0}, \overline{\alpha_{1}}, d_{i j}\right), \sigma_{\alpha}^{2}\right) L(\boldsymbol{Y}) \\
& \quad \propto \sigma_{\alpha} \exp \left[-\frac{1}{2}\left(\alpha_{1, i}^{u}-\overline{\alpha_{1}}\right)^{2} \sigma_{\alpha}^{-2}\right] L(\boldsymbol{Y})
\end{aligned}
$$

We use the Metropolis-Hastings algorithm to draw from the conditional distribution of $a_{i}, a_{i}$ is the draw of coefficients from the previous iteration, and we draw $\alpha_{1, i}^{u}$ according to $\alpha_{1, i}^{u}=\alpha_{1, i}+\Delta \alpha$, where $\Delta \alpha$ is a draw from $\mathrm{N}\left(0, \Delta^{2} \Lambda\right)$, and $\Delta$ and $\Lambda$ are chosen adaptively to reduce autocorrelation among MCMC draws following Atchade (2006),. The acceptance probability is:

$$
\operatorname{Pr}(\text { acceptance })=\min \left\{\frac{\left[\exp \left(-\frac{1}{2}\left(\alpha_{1, i}^{u}-\overline{\alpha_{1}}\right)^{2} \sigma_{\alpha}^{-2}\right)\right] L\left(\boldsymbol{Y} \mid \alpha_{1, i}^{u}\right)}{\left[\exp \left(-\frac{1}{2}\left(\alpha_{1, i}-\overline{\alpha_{1}}\right)^{2} \sigma_{\alpha}^{-2}\right)\right] L\left(\boldsymbol{Y} \mid \alpha_{1, i}\right)}, 1\right\}
$$

Step 5: $\bar{\alpha}_{1}^{u} \mid \alpha_{1, i}^{u}, \sigma_{\alpha}^{2}$, data
${\overline{\alpha_{1}}}^{u}$ is generated from a distribution $\mathrm{N}\left(\mu_{\alpha}, v_{\alpha}\right)$, where $\mu_{\alpha}=v_{\alpha}\left[\sigma_{\alpha}^{-2} \sum_{i=1}^{N} \alpha_{1, i}^{u}+v_{\alpha_{0}}^{-1} U_{0}\right], v_{\alpha}=$ $\left(N \sigma_{\alpha}^{-2}+v_{\alpha_{0}}^{-1}\right)^{-1}$. We define diffuse priors by setting $v_{\alpha 0}=100$ and $U_{0}=0$.

Step 6: $\left(\sigma_{\alpha}^{2}\right)^{u} \mid{\overline{\alpha_{1}}}^{u}, \alpha_{1, i}^{u}$

$$
\left(\left(\sigma_{\alpha}^{2}\right)^{u} \mid{\overline{\alpha_{1}}}^{u}, \alpha_{1, i}^{u}\right) \sim \operatorname{InverseGamma}\left(f_{0}+N, g_{0}^{-1}+\sum_{i=1}^{N}\left(\alpha_{1, i}^{u}-\bar{\alpha}_{1}{ }^{u}\right)^{2}\right)
$$

where we set $f_{0}=6$ and $g_{0}=1$ to be diffuse hyperprior. $f_{0}$ is the degrees of freedom, $g_{0}$ is the scale matrix of the inverse Gamma distribution.

Step 7: $\alpha_{0}^{u} \mid \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{1, i}^{u}, d_{i j}$, data

$$
f\left(\alpha_{0}^{u} \mid \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{1, i}^{u}, d_{i j}, \text { data }\right) \propto \sigma_{\alpha_{0}}^{-1} \exp \left[-\frac{1}{2}\left(\alpha_{0}^{u}-\overline{\alpha_{0}}\right)^{2} \sigma_{\alpha_{0}}^{-2}\right] L(\boldsymbol{Y})
$$

where $\overline{\alpha_{0}}$ and $\sigma_{\alpha 0}^{2}$ are diffuse priors. Because there is no closed form for this, we use the MetropolisHastings algorithm to draw from this conditional distribution of $\alpha_{0}^{u}$. The probability of accepting $\alpha_{0}^{u}$ is:

$$
\operatorname{Pr}(\text { acceptance })=\min \left\{\frac{\left[\exp \left(-\frac{1}{2}\left(\alpha_{0}^{u}-\overline{\alpha_{0}}\right)^{2} \sigma_{\alpha_{0}}^{-2}\right)\right] L\left(\boldsymbol{Y} \mid \alpha_{0}^{u}\right)}{\left[\exp \left(-\frac{1}{2}\left(\alpha_{0}-\overline{\alpha_{0}}\right)^{2} \sigma_{\alpha_{0}}^{-2}\right)\right] L\left(\boldsymbol{Y} \mid \alpha_{0}\right)}, 1\right\}
$$

We define diffuse priors by setting $\overline{\alpha_{0}}=0$ and $\sigma_{\alpha_{0}}^{2}=30$.
Step 8: Generate $a_{i}^{u}, b_{i}^{u}$ :

$$
\begin{aligned}
& f\left(a_{i}^{u}, b_{i}^{u} \mid \boldsymbol{\beta}_{i}^{u}, \Sigma_{a b}, \alpha_{0}^{u}, \alpha_{1, i}^{u}, d_{i j}, \text { data }\right) \\
& \quad \propto \mathrm{N}\left(\left(a_{i}^{u}, b_{i}^{u} \mid \boldsymbol{\beta}_{i}^{u}, \alpha_{0}^{u}, \alpha_{1, i}^{u}, d_{i j}\right), \Sigma_{a b}\right) L(\boldsymbol{Y}) \\
& \quad \propto\left|\Sigma_{a b}\right|^{-\frac{1}{2}} \exp \left[-\frac{1}{2}\left(a_{i}^{u}, b_{i}^{u}\right) \Sigma_{a b}^{-1}\left(a_{i}^{u}, b_{i}^{u}\right)^{\prime}\right] L(\boldsymbol{Y})
\end{aligned}
$$

Because this distribution does not have a closed form, we use the Metropolis-Hastings algorithm to draw from the conditional distribution of $a_{i}, b_{i}: a_{i}, b_{i}$ is the draw of the random effect from the previous iteration, and we draw $a_{i}^{u}, b_{i}^{u}$ by $\left[\begin{array}{l}a_{i}^{u} \\ b_{i}^{u}\end{array}\right]=\left[\begin{array}{l}a_{i} \\ b_{i}\end{array}\right]+\Delta\left[\begin{array}{l}a \\ b\end{array}\right]$, where $\Delta\left[\begin{array}{l}a \\ b\end{array}\right]$ is a draw from $\mathrm{N}\left(0, \Delta^{2} \Lambda\right)$, and $\Delta$ and $\Lambda$ are chosen adaptively to reduce autocorrelation among MCMC draws following Atchade (2006). The probability of accepting this $\left[\begin{array}{c}a_{i}^{u} \\ b_{i}^{u}\end{array}\right]$, the updated value for $\left[\begin{array}{l}a_{i} \\ b_{i}\end{array}\right]$ is:

$$
\operatorname{Pr}(\text { acceptance })=\min \left\{\frac{\left[\exp \left(-\frac{1}{2}\left(a_{i}^{u}, b_{i}^{u}\right) \Sigma_{a b}^{-1}\left(a_{i}^{u}, b_{i}^{u}\right)^{\prime}\right)\right] L\left(\boldsymbol{Y} \mid a_{i}^{u}, b_{i}^{u}\right)}{\left[\exp \left(-\frac{1}{2}\left(a_{i}, b_{i}\right) \Sigma_{a b}^{-1}\left(a_{i}, b_{i}\right)^{\prime}\right)\right] L\left(\boldsymbol{Y} \mid a_{i}, b_{i}\right)}, 1\right\}
$$

Step 9: $\Sigma_{\mathrm{ab}}^{\mathrm{u}} \mid a_{i}^{u}, b_{i}^{u}$

$$
\left(\Sigma_{\mathrm{ab}}^{\mathrm{u}} \mid a_{i}^{u}, b_{i}^{u}\right) \sim I W_{2}\left(7+N, G_{0}^{-1}+\sum_{i=1}^{N}\left(a_{i}^{u}, b_{i}^{u}\right)\left(a_{i}^{u}, b_{i}^{u}\right)^{\prime}\right)
$$

Step 10: $d_{i j}^{u}, d_{j i}^{u} \mid \alpha_{0}^{u}, \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{1, i}^{u}, \sigma_{d}^{2}$, data

$$
\begin{aligned}
& f\left(d_{i j}^{u}, d_{j i}^{u} \mid \alpha_{0}^{u}, \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{1, i}^{u}, \sigma_{d}^{2}, \text { data }\right) \\
& \quad \propto \mathrm{N}\left(\left(d_{i j}^{u}, d_{j i}^{u} \mid \alpha_{0}^{u}, \boldsymbol{\beta}_{i}^{u}, a_{i}, b_{i}, \alpha_{1, i}^{u}\right), \sigma_{d}^{2}\right) L(\boldsymbol{Y}) \\
& \quad \propto \sigma_{d}^{-1} \exp \left[-\frac{1}{2}\left(d_{i j}^{u}+d_{j i}^{u}\right)^{2} \sigma_{d}^{-2}\right] L(\boldsymbol{Y})
\end{aligned}
$$

We use the Metropolis-Hastings algorithm to draw from this conditional distribution of $d_{i j}^{u}$ and $d_{j i}^{u}$ : $d_{i j}$ and $d_{j i}$ are the draw of the unobservable similarity effects from the previous iteration, and we draw $d_{i j}^{u}, d_{j i}^{u}$ by $\left[\begin{array}{l}d_{i j}^{u} \\ d_{j i}^{u}\end{array}\right]=\left[\begin{array}{l}d_{i j} \\ d_{j i}\end{array}\right]+\Delta \boldsymbol{d}$, where $\Delta \boldsymbol{d}$ is a draw from $\mathrm{N}\left(0, \Delta^{2} \Lambda\right)$, and $\Delta$ and $\Lambda$ are chosen adaptively to reduce autocorrelation among MCMC draws following Atchade (2006). The probability of accepting $\left[\begin{array}{l}d_{i j}^{u} \\ d_{j i}^{u}\end{array}\right]$ is:

$$
\operatorname{Pr}(\text { acceptance })=\min \left\{\frac{\left[\exp \left(-\frac{1}{2}\left(d_{i j}^{u}+d_{j i}^{u}\right) \sigma_{d}^{-2}\right)\right] L\left(\boldsymbol{Y} \mid d_{i j}^{u}, d_{j i}^{u}\right)}{\left[\exp \left(-\frac{1}{2}\left(d_{i j}+d_{j i}\right) \sigma_{d}^{-2}\right)\right] L\left(\boldsymbol{Y} \mid d_{i j}, d_{j i}\right)}, 1\right\}
$$

Step 11: Generating $\sigma_{d}^{u}$

$$
\left(\sigma_{d}^{u} \mid d_{i j}^{u}, d_{j i}^{u}\right) \sim \mathrm{IW}_{1}\left(1+N(N-1), 1+\sum_{i=1}^{N} \sum_{j=1, j \neq i}^{N}\left(d_{i j}^{u}+d_{j i}^{u}\right)^{2}\right)
$$

Step 12: If convergence is not yet reached, go to Step 1.

[^0]:    ${ }^{1}$ We start with one node in the network at time $t=0$. Then, for $T=5000$ time periods, at each time period, we add one node with one tie that links the new node to one node already present in the network. The probability that a new node will link to node $i$ depends on the degree of node $i$ : Pr(link to node $i$ ) $=$ Degree $_{i} / \sum_{j}$ Degree $_{j}$. Note that the degree distribution of a scale-free network follows a power law, which implies that it has a long tail.

[^1]:    ${ }^{* * *},{ }^{* *}$ and $*$ denote that the $99 \%$ credible interval, the $95 \%$ credible interval, and the $90 \%$ credible interval, respectively,
